Introduction:

- Visual search is a ubiquitous part of life, yet searchers sometimes fail to respond to clearly visible targets[1].
- Errors are commonly classified as **scanning, recognition** and **decision** errors, based on searcher's eye movements[2].
- Recognition errors, which occur despite searchers fixating the target, can indicate a failure in a variety of cognitive mechanism, including perception, attention, and memory[1, 3].
- Previously reported rates of fixated-but-missed errors vary remarkably across studies, from 2-34% depending on various stimulus properties[4-5].
- Here, we examine how **presentation mode**, **target category** and **target rotation** influence the probability of missing a fixated target ($P[\text{recognition error} \mid \text{on target}]$), while minimizing memory- and decision-related confounds.

Methods:

Stimulus

- 180 icons in array
- All trials have 1-3 targets
- Each specific target appears 0-2 times
- 3 trial types
- 6 target categories
  Human Face, Human Body Part, Animal Face, Animal body, Hand-Made Object, Natural Object
- Target rotation $[-20°, 20°]$

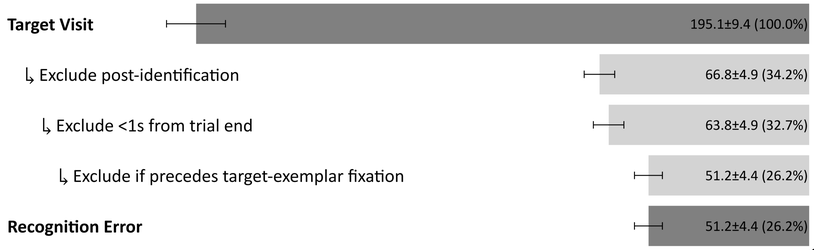
Participants & Apparatus

- $N = 12$ Participants
- 60 trials/participant (10/block)
- Tobii Pro Spectrum @ $600Hz$

Hierarchical Bayesian Model

$$P[\text{recognition error}] \sim C(\text{trial type}) \cdot C(\text{target category}) \cdot |\text{target angle}| + (1 \mid \text{subject})$$

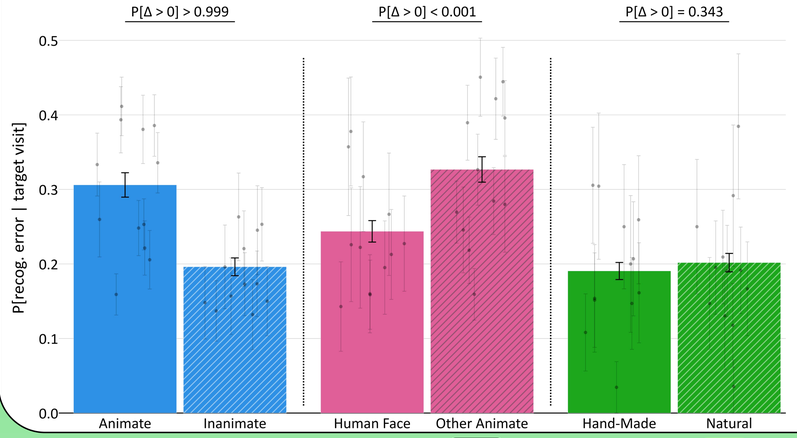
Defining Recognition Errors



Results:

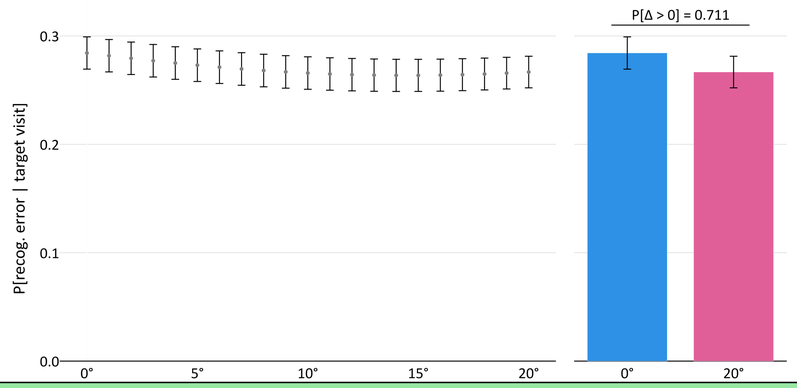
Semantic Effect

- **Animate** targets were less recognized than **inanimate** targets.
- Among **animate** targets, **human faces** were more recognized.
- No difference between **hand-made** and **natural** objects.



Rotation Effect

- Target angles collapsed over counter- and clock-wise rotation
- No difference between **upright** (0°) and **rotated** (±20°)



Visual Format Effect

- Grayscale images yielded lower recognition than color images.
- Background noise did not impair recognition.
